

Method of controlling a circuit arrangement for the AC power supply of a plasma display panel

The invention relates to a method of controlling a circuit arrangement for an AC voltage supply of a plasma display panel (PDP), more particularly a sustain driver. PDPs are flat picture screens or televisions which are produced with the aid of plasma technology. Light is then generated by small gas discharges between two glass plates. In principle, small,
5 individual plasma discharge lamps are driven via electrodes arranged horizontally and vertically. Considerable electronic circuitry is necessary for operating the plasma cells. The so-called sustain driver whose task is to supply trapezoidal AC voltages to the self-capacitances of the plasma cells takes up the largest surface area. The electrodes of the plasma cells are then connected to the outputs of two half bridges of a commutation circuit.
10 The two outputs of the half bridges may apply the positive input voltage $+U_0$, the negative input voltage $-U_0$ or the zero voltage (short-circuit of the electrode terminals) to the electrodes of the plasma cells. The two half bridges are supplied with an auxiliary voltage which corresponds to 50% of the input voltage U_0 . For the cells to be ignited, a rapid change from the positive to the negative voltage and vice versa is to take place on the electrodes. For
15 this purpose, the voltage output of a half bridge converter is alternately connected to the positive voltage pole, whereas the other voltage output is applied to the minus pole. In so far as the two transitions are directly consecutive, the voltage on the plasma cells changes very rapidly from a negative to a positive value of the input voltage U_0 . As a result, the cells are ignited. To avoid losses which arise during the direct charging and discharging of the
20 capacitor of the plasma cell, the sustain driver is usually structured as a resonant switched-mode power supply in which the charging and discharging of the capacitor of the plasma cell takes place free of losses in principle. When this principle of resonance is realized and converted, the oscillation is attenuated because the coils, supply lines and semiconductor switches represent parasitic resistances. This leads to the fact that the voltage on the plasma
25 cell does not completely jump to the input voltage or zero, respectively. In consequence, the bridge transistors are included in the circuit leading to the development of a loss-affected recharging or residual discharge. The currents linked with this are flowing with each recharging even when the plasma cells should not light up. The loss-affected recharging or

residual discharge further causes problems with respect to the electromagnetic compatibility (EMV). The influence of the parasitic resistances is noticeable as a characteristic stage in the oscillation curve of the plasma voltage. Once the charging current for the capacitor of the plasma cell has reached its output value, thus substantially zero, the characteristic stage
5 appears in the oscillation curve (here: jump from "substantially zero" to "zero" in the oscillation curve. Before the oscillation operation the two transistors of the half bridge are turned off so that a change of the voltage on the capacitor of the plasma cell can take place).

This known symmetrical commutation circuit can be easily manufactured as regards the circuitry. Therefore, it is an object of the invention to provide a method of
10 controlling a circuit arrangement for the AC power supply to a plasma display panel which leads to a compensation of the losses caused by the parasitic resistances and to a reduction of the electromagnetic interference.

The object is achieved, on the one hand, in that at the moment when the first auxiliary transistor T11 is turned on, thus at the beginning of the charging operation of the capacitor (Cp), the first bridge transistor T1 of the half bridge is turned off and the second
15 bridge transistor T2 of the half bridge continues to be turned on for a predefined delay time and is turned off after the delay time t_v has elapsed. As a result the cell voltage U_p first remains equal to zero ($U_p = 0$). Meanwhile, the charging current $i_1(t)$ linearly increases in the first coil L1. The moment the second bridge transistor T2 is turned off, the resonant charging
20 operation of the capacitor Cp of the plasma cell commences. Since the current of the plasma cell is now equal to the charging current i_1 , it already has an initial value when the capacitor Cp is rendered conductive, so that the capacitor Cp is charged more rapidly. When the time t_v of the delayed turn-off is adapted and the first coil L1 is pre-charged in an adapted fashion, the capacitor Cp will be completely charged from zero to the input voltage U_0 within the next
25 half sine-wave oscillation.

The object of the invention will also be achieved in that at the moment when the second auxiliary transistor T12 is turned on, thus at the beginning of the discharge operation of the capacitor Cp, the second bridge transistor T2 of the half bridge is turned off and the first bridge transistor T1 of the half bridge continues to be turned on for a predefined
30 delay time and is turned off after the delay time t_v has elapsed. As a result, the charging current $i_2(t)$ in the second coil L2 increases linearly. At the moment when the first bridge transistor T1 is turned off, the resonant discharge operation of the capacitor Cp of the plasma cell commences and is terminated when the half sine-wave oscillation ($U_p = 0$) has ended.

For reasons of symmetry the current balance on the capacitor C_s is compensated ($U_s = U_0/2$) according to the invented method of controlling a charging and discharging operation. An embodiment of the circuit arrangement according to the invention will be further explained with reference to the following Figures, in which according to the state of the art is shown in

Fig. 1 the transistor bridge for generating a cell voltage with a conventional commutation circuit (for clarity only the commutation circuit of a half bridge is shown);

Fig. 2 shows the influence of the parasitic resistances on the cell voltage U_p of the capacitor C_p of the plasma cell.

The invention further shows in:

Fig. 3 the position of the essential elements of the commutation circuit during the charging operation for an instant $t < t_v$;

Fig. 4 the position of the essential elements of the commutation circuit during the charging operation for an instant $t > t_v$;

Fig. 5 a diagram showing the charging operation of the capacitor C_p of the plasma cell with a compensation of the influence of the parasitic resistances;

Fig. 6 the position of the essential elements of the commutation circuit during the discharging operation for an instant $t < t_v$;

Fig. 7 the position of the essential elements of the commutation circuit during the discharging operation for an instant $t > t_v$; and

Fig. 8 a diagram of a discharging operation of the capacitor C_p of the plasma cell with a compensation of the influence of the parasitic resistances.

The transistor bridge shown in Fig. 1 with a conventional commutation circuit in essence comprises two half bridges. The electrodes of the plasma cells are connected to its outputs. Depending on the drive of the bridge transistors T1, T2, T3 and T4 the positive input voltage $U_p = +U_0$, the negative input voltage $U_p = -U_0$, or the zero voltage $U_p = 0$ (short-circuit of the electrode terminals) is present on the outputs of the two half bridges. For the plasma cells to ignite, there must be a rapid change from the positive to the negative voltage and vice versa. For this purpose, the voltage output of a half bridge converter is alternately applied to the positive voltage pole, while the respective other voltage output is applied to the negative voltage pole. In so far as the two transitions directly follow each other, the voltage on the plasma cells very rapidly changes from the negative to the positive value of the input voltage U_0 . This causes the plasma cells to be ignited in so far as additionally an addressing

is made. The ignition current for light generation then flows via the diagonal first and fourth transistors T1 and T4 or T2 and T3 of the bridge circuit. Each half bridge comprises an oscillation circuit with Fig. 1 only showing one half bridge. The single oscillation circuit comprises a capacitor C_p of the plasma cell and the inductance L1 for the charging operation and L2 for the discharging operation. The charging operation is initiated by means of an auxiliary transistor T11 which is connected in series to the inductance L1 and the discharging operation is initiated by the auxiliary transistor T12 which is connected in series to the inductance L2. The diodes D1 and D2 arranged between the auxiliary transistors T11, T12 and the inductances provide that each time only one charging or discharging current occurs in a semi-oscillation. In a symmetrical arrangement and drive of the commutation circuit the half input voltage U_0 appears on the capacitor C_s substantially as an auxiliary voltage U_h , which means $U_h = U_0/2$. The capacitor C_s is then selected so large that there is no change of the capacitor voltage on the capacitor C_s , i.e. $C_s \gg C_p$ within one switching period. If now the empty capacitor C_p of the plasma cells is connected to the capacitor C_s charged with the auxiliary voltage U_h via the auxiliary transistor T11 used as a switch, an oscillation operation will arise which is limited to a sine oscillation of the charging current I_1 . The termination after a half period is effected by the diode D1 in the circuit that allows only the positive wave. At the same time, together with the sine oscillation of the charging current I_1 , a cosine-shaped cell voltage U_p builds up on the capacitor C_p of the plasma cell, which cell voltage U_p rises from zero to approximately double the value of the auxiliary voltage U_h on the capacitor C_s , which approximately corresponds to the input voltage U_0 . As a result of the parasitic resistances determined by the coils, supply lines and semiconductor circuit, the voltage U_p , however, is attenuated and does not reach the value of the input voltage U_0 during the charging operation.

The discharging of the capacitor C_p of the plasma cell with the aid of the oscillation circuit comprising the capacitor C_p and the inductance L2 is effected only substantially free of losses because of the parasitic resistances. In this case the oscillation operation is initiated when the second auxiliary transistor T12 is turned on.

After the oscillation operation has ended, either the upper or the lower bridge transistor of the half bridge (T1, T2) is turned on. Since the cell voltage U_p on the capacitor C_p of the plasma cell has not reached the value of the input voltage U_0 as a result of the attenuated oscillation, the recharging current I_p will flow when the half bridge T1 is turned on. The jump from U_p to U_0 of the maximum voltage that can be reached during the charging operation at the switch-on time of the bridge transistor T1 is shown in Fig. 2. The

normalized representation of the influence of the parasitic resistances during the charging operation in Fig. 2 is related to the input voltage U_0 as regards the cell voltage U_p and as regards the charging current I_1 to the input voltage U_0 divided by the impedance Z_0 , where Z_0 is formed by

5

$$Z_0 = \sqrt{\frac{L_0}{C_p}}$$

The recharging shown in Fig. 2 as a jump in the voltage curve is a residual discharge during the discharging operation. The cell voltage U_p then reaches the zero value only substantially. The jump to zero takes place when the transistor T2 is turned on. The inherent currents are flowing with each oscillation even when the plasma cells should not light up. The recharging or residual discharging causes additional losses and problems with the electromagnetic compatibility (EMV).

Fig. 3 shows the position of the essential circuit elements for the instant $t < t_v$. When the first auxiliary transistor T11 is turned on, thus at the beginning of the charging operation of the capacitor C_p , the first bridge transistor T1 of the half bridge is turned off; the bridge transistor T1 in Fig. 3 is shown as an open switch. The second bridge transistor T2 of the half bridge continues to be turned on for a predefined delay time. With the conventional method of controlling the commutation circuit the two bridge transistors (T1, T2) of the half bridge are turned off prior to each oscillatory operation i.e. prior to one of the auxiliary capacitors T1 and T2 being switched on and the flowing of the charging or discharging current, because otherwise no change of the cell voltage U_p takes place at the capacitor C_p . According to the method according to the invention the current circuit comprises an auxiliary voltage U_h for the instant $t < t_v$, which auxiliary voltage U_h is about half the input voltage U_0 and is present at the capacitor C_s , comprises the first auxiliary transistor T11, the first coil L1 and comprises the bridge transistor T2. The cell voltage U_p continues to be zero because the capacitor C_p does not build up any capacitance.

Fig. 4 shows the position of the essential circuit elements in accordance with the method according to the invention of controlling a circuit arrangement for supplying the AC voltage to a plasma display panel for the instant $t > t_v$. The second bridge transistor T2 is shown as an open and thus currentless switch. The circuit thus comprises for $t > t_v$ the capacitor C_s which is here shown as a voltage source having 50% of the value of the input voltage $U_h = U_0/2$, the first auxiliary transistor T11, the first coil L1 and the capacitor C_p .

Fig. 5 is a diagram showing the charging current and the cell voltage over time t . The current linearly rises with time $t < t_v$. This is caused by the conducting switch T2 for $t < t_v$. For $t > t_v$ the rise in voltage is steeper than with the conventional method of the commutation circuit control, because the charging current $i_1(t)$ in the first coil L1 has already
5 been partly built up. Since the capacitor C_p is charged from $t > t_v$ onwards, the voltage difference across the first coil L1 diminishes and thus also the rise in voltage. The charging current i_1 then according to the invention reaches a maximum current $i_{1\max}$ which exceeds the maximum current in Fig. 2 of the state of the art. As a result, the capacitor C_p is charged to a higher voltage $u_p(t)$ during the sinusoidal half oscillation of the charging current $i_1(t)$.

10 The described method according to the invention ensures that at the end of the charging operation the cell voltage U_p at the capacitor C_p has reached the value of the input voltage U_0 . As a result, the transistor T1 of the half bridge is turned on voltage-free and less high-frequency interference and losses will arise.

The object is also achieved, however, by a method according to the invention
15 in which it is ensured that at the end of the discharging operation the cell voltage U_p on the capacitor C_p has substantially reached the zero value and the second bridge transistor T2 of the main bridge is turned on voltage-free.

Fig. 6 shows the position of the essential elements of the commutation circuit at the discharging operation for an instant $t < t_v$. By turning on the second auxiliary transistor T12, thus at the beginning of the discharging operation of the capacitor C_p , the second bridge
20 transistor T2 of the half bridge is turned off; in Fig. 6 the second bridge transistor T2 is shown as an open switch. The first bridge transistor T1 of the half bridge continues to be turned on for a predefined delay time t_v . In accordance with the invented method of discharging the circuit comprises an auxiliary voltage U_h for the instant $t < t_v$, which
25 auxiliary voltage is about 50% of the input voltage U_0 and is present at the capacitor C_s , comprises the second auxiliary transistor T12, the second coil L2 and the bridge transistor T1. The cell voltage U_p continues to be zero because the capacitor C_p does not build up any capacitance.

Fig. 7 shows the position of the essential elements of the commutation circuit
30 in accordance with the method according to the invention of controlling a circuit arrangement for the supply of AC voltage of a plasma display panel for an instant $t > t_v$. The first bridge transistor T1 is now also shown as an open switch and is therefore currentless. The circuit thus comprises during the discharging for $t > t_v$ the capacitor C_s , which is shown here as a

voltage source with 50% of the value of the input voltage $U_h = U_0/2$, the second auxiliary transistor T12, the second coil L2 and the capacitor Cp.

Fig. 8 is a diagram showing the discharging current $i_2(t)$ and the cell voltage U_p over time t . The current linearly rises with time $t < t_v$. This is caused by the conducting switch T1 for $t < t_v$. For $t > t_v$ the voltage drop is steeper than in the conventional method of controlling the commutation circuit because the discharging current $i_2(t)$ in the second coil L2 has already been partly built up. Since the capacitor Cp discharges as from $t > t_v$, the voltage difference across the second coil L2 diminishes and thus also the rise of current. The discharging current i_2 then according to the invention reaches a maximum current i_{2max} which exceeds the maximum current in Fig. 2 of the prior art. As a result, during the sinusoidal half oscillation of the discharging current $i_2(t)$ the capacitor Cp is discharged to a lower voltage $u_p(t)$.

The diagrams in Figs. 5 and 8 are shown in normalized fashion as is the diagram in Fig. 2. $u_p(t)$ is then related to the input voltage U_0 and the charging current $i_1(t)$ or discharging current $i_2(t)$, respectively, is related to the input voltage U_0 divided by the impedance Z_0 , where Z_0 is formed by:

$$Z_0 = \sqrt{\frac{L_0}{C_p}}$$

In an embodiment of the invention the delay time t_v is fixedly set, for example, to 1/8 of the oscillatory period. The delay time t_v is arranged such that the pre-charging of the coils L1, L2 is sufficiently large for the charging current I_1 or discharging current I_2 , respectively to be allowed to rise to a value that exceeds the input voltage U_0 divided by the impedance I_0 . The fixed setting may also be used in repetitive work. The MOSFET (Metal Oxide Semiconductor-Field Effect Transistor) switch used as an inner diode in this example of embodiment prevents a rise of the cell voltage U_p beyond the input voltage U_0 .

In another embodiment of the invention the delay time t_v is not fixedly set but is corrected automatically. As a measure for the correction the voltage difference U_{diff} between the cell voltage U_p and the input voltage U_0 i.e. $U_{diff} = U_p - U_0$ If the voltage difference at the instant when the bridge transistor T1 is turned on exceeds zero, the delay time t_v for the next switching period is reduced. The voltage difference may become positive because the inner diode of the transistor will not become conductive until a small positive

voltage is applied. If the voltage difference at the instant when the first bridge transistor T1 is turned on is smaller than zero, the delay time t_v for the next switching period is extended.

The sign of the differential voltage may preferably be determined by a voltage comparator.

- The method according to the invention of controlling a circuit arrangement for
- 5 the AC power supply of a plasma display panel leads to a substantially exact reaching of the voltage level of the cell voltage when the current in the respective coil is preset correctly.
